19

19 **Abstract**

20 The difference between cloud-top altitude Z_{top} and infrared effective radiating height Z_{eff}
21 for optically thick ice clouds is examined using April 2007 data taken by the Cloud-Aerosol
22 Lidar and Infrared Pathfinder Satellite Observations (CALIPSO) and the Moderate-Resolution
23 Imaging Spectroradiometer (MODIS). For even days, the difference ΔZ between CALIPSO Z_{top}
24 and MODIS Z_{eff} is 1.58 ± 1.26 km. The linear fit between Z_{top} and Z_{eff} , applied to odd-day data,
25 yields a difference of 0.03 ± 1.21 km and can be used to estimate Z_{top} from any infrared-based Z_{eff}
26 for thick ice clouds. Random errors appear to be due primarily to variations in cloud ice-water
27 content (IWC). Radiative transfer calculations show that ΔZ corresponds to an optical depth of
28 ~ 1 , which based on observed ice-particle sizes yields an average cloud-top IWC of $\sim 0.015 \text{ gm}^{-3}$,
29 a value consistent with in situ measurements. The analysis indicates potential for deriving cloud-
30 top IWC using dual-satellite data.

31

31 **1. Introduction**

32 Spectral bands in the infrared (IR) atmospheric window (10-12 μm) are routinely used to
33 estimate cloud top heights from passive satellite sensors [e.g., *Rossow and Schiffer*, 1999; *Minnis*
34 *et al.*, 1995]. IR radiation is relatively transparent to the atmosphere above the cloud, and the
35 observed 11- μm brightness temperature T_{11} can be matched to local temperature soundings to
36 find the cloud height. Although it is recognized that the effective radiating temperature of
37 optically thin clouds corresponds to some level below cloud top, it is commonly assumed that
38 optically thick clouds have sharp boundaries and optically thick edges. They are generally treated
39 as blackbodies, and so T_{11} is assumed to be equivalent to the cloud-top temperature plus a small
40 correction for atmospheric absorption and cloud particle scattering. Recent research has
41 demonstrated, however, that even deep convective clouds do not have such sharply defined
42 boundaries in the IR spectrum. For example, *Sherwood et al.* [2004] found that cloud tops
43 derived from the eighth Geostationary Operational Environmental Satellite (GOES-8) were 1-2
44 km below the convective cloud tops detected by lidar data collected over Florida. Those and
45 other results require new approaches to interpret the infrared brightness temperatures of optically
46 thick clouds. Measurements from active sensors combined with passive infrared radiances are
47 needed to address this outstanding problem.

48 Until recently, active remote sensing of optically thick clouds has been extremely limited.
49 Ground-based radars and lidars profile the atmosphere continuously, but observe at only one
50 location. They are also unlikely to detect the physical tops of optically thick ice clouds because
51 lidars can only penetrate to optical depths of less than about 3 into the cloud and cloud radars
52 often have no returns from smaller ice crystals common at the tops of such clouds. Active
53 sensors aboard aircraft can sample a larger area during field campaigns and can outline the tops

54 of the clouds, but they collect data for only a few days over the duration of a given experiment.
55 With the 2006 launch of the Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations
56 (CALIPSO) satellite into orbit behind the *Aqua* satellite in the A-Train, coincident and nearly
57 simultaneous global lidar and infrared radiance measurements are now available. This study uses
58 the measurements from CALIPSO and the *Aqua* Moderate-Resolution Imaging
59 Spectroradiometer (MODIS) to develop a new method to estimate the physical top of optically
60 thick ice clouds from passive IR imager data.

61

62 **2. Data and Methodology**

63 Like *Aqua*, CALIPSO follows a Sun-synchronous orbit with an approximately 1330-LT
64 equatorial crossing time ~ 90 s behind *Aqua*. Because CALIPSO is offset by $7\text{-}18^\circ$ east of *Aqua*,
65 the *Aqua* sensors typically observe the CALIPSO ground track at viewing zenith angles VZA of
66 $9\text{-}19^\circ$. The primary instrument on CALIPSO is the Cloud Aerosol Lidar with Orthogonal
67 Polarization (CALIOP), which has 532 and 1064-nm channels for profiling clouds and aerosols
68 [Winker *et al.*, 2007]. The CALIOP footprints are nominally 70-m wide and sampled every 330
69 m. This instrument allows the global characterization of cloud vertical structure with vertical
70 resolutions up to 30 m. The CALIPSO data used here are the April 2007 Version 1.21 1/3 km
71 cloud height products [Vaughan *et al.*, 2004].

72 Cloud properties derived from 1-km *Aqua* MODIS radiances using the Clouds and the
73 Earth's Radiant Energy System (CERES) project cloud retrieval algorithms [Minnis *et al.*, 2006]
74 were matched with CALIOP data (see Sun-Mack *et al.* [2007]). The CERES cloud properties are
75 determined from the radiances using updated versions of the daytime Visible Infrared Solar-
76 Infrared Split Window Technique (VISST) and the nighttime Solar-infrared Infrared Split-

77 window Technique (SIST) [Minnis *et al.*, 1995]. The products include cloud temperature, height,
78 thermodynamic phase, optical depth, effective ice crystal diameter D_e , and other cloud
79 properties.

80 The VISST/SIST first determines the effective radiating temperature T_{eff} , which
81 corresponds to a height somewhere within the cloud Z_{eff} [e.g., Minnis *et al.*, 1990]. For clouds
82 above 500 hPa, Z_{eff} is determined by matching T_{eff} to a local atmospheric temperature sounding.
83 For optically thin ice clouds, an empirical correction is applied to estimate the true cloud-top
84 temperature T_{top} based on cloud emissivity [Minnis *et al.*, 1990]. The cloud-top altitude Z_{top} for
85 those clouds is the lowest level in the sounding corresponding to T_{top} . Optically thick clouds are
86 assumed to have sharp boundaries and, therefore, most IR radiation reaching the satellite sensor
87 is emitted by the uppermost part of the cloud. In optically thick cases, VISST and SIST assume
88 that T_{eff} is equivalent to T_{top} and $Z_{top} = Z_{eff}$. VISST accounts for the effects of infrared scattering
89 effects so, for these clouds, T_{eff} is slightly greater than T_{11} .

90 Matched VISST and CALIPSO data from every even day during April 2007 were
91 selected to develop a relationship between the effective and physical cloud-top heights of
92 optically thick ice clouds. Clouds with effective emittance exceeding 0.98 (visible optical depth τ
93 > 8) are considered to be optically thick. This definition includes a wide variety of clouds
94 including thick cirrus and convective cloud anvils and cores. Polar clouds (latitudes $> 60^\circ$) were
95 excluded to avoid mischaracterizing them over ice and snow. The method is tested using the odd-
96 day April 2007 MODIS-CALIPSO non-polar matched data.

97 **3. Cloud-Top Height Correction**

98 Figure 1 shows CALIOP backscatter intensity profiles (Figure 1a) and scene
99 classifications for a 1-h segment of a 27 April 2007 CALIPSO orbit. It began in darkness over

100 North America, crossed the Pacific and Antarctica into daylight, and ended in the Indian Ocean.
 101 The scene classifications (Figure 1b), which show cloud and aerosol locations, are overlaid with
 102 black dots corresponding to Z_{top} from CERES-MODIS for optically thick, single-layer ice
 103 clouds. These are evident as the gray areas underneath the clouds. The absence of black dots
 104 indicates that the cloud is liquid water, multilayered, or optically thin cirrus. Generally, Z_{top} is 1-
 105 2 km below the CALIPSO top Z_{topCAL} .

106 The cloud-top height pairs for all even days during April 2007 are plotted in Figure 2 as
 107 density scatter plots with linear regression fits. In Figure 2a, the average difference between the
 108 15,367 Z_{topCAL} and their Z_{eff} pairs increases slightly with increasing altitude. The mean difference,
 109 $Z_{eff} - Z_{topCAL}$, is -1.58 ± 1.26 km. The linear regression fit plotted over the data,

110

$$111 \quad Z_{top} = 1.094 Z_{eff} + 0.751 \text{ km}, \quad (1)$$

112

113 yields a squared linear correlation coefficient $R^2 = 0.89$. According to Eq(1), the difference ΔZ
 114 between Z_{top} and Z_{eff} rises from ~ 1.25 km for $Z_{eff} = 5$ km up to more than 2 km for $Z_{eff} > 14$ km.

115 Applying Eq(1) to Z_{eff} in Figure 1b yields the new values in Figure 1c that are mostly
 116 very close to the corresponding Z_{topCAL} . Figure 2b compares the 15,170 values of Z_{topCAL} and Z_{top}
 117 computed with Eq (1) for all April 2007 odd-day data. The data corresponding to $Z_{topCAL} > 3$ km
 118 are centered along the line of agreement, while lower cloud heights are overestimated. The
 119 correction yields a mean difference of -0.03 ± 1.21 km and the results are more correlated than
 120 the even-day data, having $R^2 = 0.91$. This empirical correction effectively eliminates the bias and
 121 slightly reduces the random error in the estimated Z_{top} . The correction is robust in that it applies

122 well to two independent datasets. The Z_{top} estimates were not constrained to be below the
123 tropopause.

124 For $Z_{eff} < 3$ km, the data tend to be centered on the line of agreement in Figure 2a
125 indicating that no correction is needed. The correction results in unphysical values at those
126 altitudes and should not be applied. This overestimation is due to uncertainties in the
127 atmospheric profile of temperature in the lower layers (e.g., *Dong et al.* [2008]) or to the
128 misclassification of supercooled-liquid water or mixed-phase clouds as ice clouds by the
129 CERES-MODIS *Aqua* algorithm. The basic assumption that the correction is for ice clouds
130 would be violated for those and other low-level pixels. The tops of water clouds are unlikely to
131 be more than a few hundred meters above Z_{eff} [e.g., *Dong et al.*, 2008]. For low clouds, a better
132 estimate of Z_{eff} and a more accurate phase classification are needed before applying a correction
133 to obtain Z_{top} . That effort is beyond the scope of this paper.

134 To minimize the impact of low-altitude temperature and phase uncertainties in the
135 retrievals, the regression was also performed using the even-day data (13,046 samples) only for
136 ice clouds with effective pressures, $p_{eff} < 500$ hPa. The resulting fit is

137

$$138 \quad Z_{top} = 1.041 Z_{eff} + 1.32 \text{ km.} \quad (2)$$

139

140 Applying Eq (2) to odd-day clouds having $p_{eff} < 500$ hPa yields an average difference of $-0.08 \pm$
141 1.15 km. This difference is nearly the same as the average difference of -0.13 ± 1.14 km that
142 would be obtained by applying Eq (1) to the same odd-day dataset. If Eq (2) is used to estimate
143 Z_{top} for *all* of the odd-day data, the mean difference is 0.07 ± 1.24 km. The results are essentially

144 the same for both fits. The 500-hPa cutoff effectively eliminates the low-cloud heights that
145 would be overestimated by estimating Z_{top} from Z_{eff} with either correction.

146

147 **4. Discussion**

148 The instantaneous differences can mainly be attributed to uncertainties in the temperature
149 profiles used to convert temperature to altitude, spatial mismatches in the data, VZA
150 dependencies, and variations in cloud microphysics. The small portions of the satellite pixel
151 sampled by the narrow lidar footprint can cause some significant differences if cloud height
152 varies within the pixel. Errors in the temperature profiles can move Z_{eff} up or down. For example,
153 some of the Z_{eff} values between 6 and 14 km in Figure 2a are lower than the corresponding
154 values of Z_{topCAL} and account for ~ 1 km of the range in ΔZ . It could also account for some of the
155 extreme overestimates. This type of error will occur some of the time since the temperature
156 profiles are based on numerical weather analysis assimilation of temporally and spatially sparse
157 observations. The VZA has little impact here.

158 To examine the impact of cloud microphysics on ΔZ , radiative transfer calculations were
159 performed by applying the Discrete Ordinates Radiative Transfer (DISORT; *Stamnes et al.*
160 [1988]) method to an example case. For a given layer, the layer thickness can be expressed as

161

$$162 \quad \Delta z_i = 4 \delta D_{ei} \Delta \tau_i / 6 Q IWC_i, \quad (3)$$

163

164 where $\Delta \tau_i$ is the visible optical depth for cloud layer i , the visible extinction efficiency Q has a
165 value of ~ 2 (e.g., *Minnis et al.* [1998]), IWC_i is the layer ice water content, the density of ice is δ
166 $= 0.9 \text{ g cm}^{-3}$, and D_{ei} is the effective diameter of the ice crystals in the cloud layer.

167 The DISORT calculations assumed an 8.0-km thick cloud extending to 13 km in a
168 tropical atmosphere. The cloud was divided into 198 layers with Δz_i decreasing from less than
169 110 m at the base to 40 m at the top. The bottom-layer optical depth was specified at 12 to ensure
170 that the cloud is optically thick. Calculations were then performed to compute T_{eff} for a range of
171 IWC and three values of D_e . Three IWC profiles were examined: IWC decreasing linearly from
172 the layer above the base to cloud top, uniform IWC, and IWC increasing from the first layer
173 above the base to the top. The mean IWC of the entire cloud above the bottom layer is the same
174 for all three cases. Z_{eff} was determined from T_{eff} and the simulated cloud-top height correction
175 was computed as $13 \text{ km} - Z_{eff}$. The optical depth (IWC) of the layer above Z_{eff} , the top layer, is the
176 sum of τ_i (IWC_i) above Z_{eff} . Figure 3 shows the results for both uniform and decreasing-with-
177 height IWC. Assuming that ~ 1.5 km of the range in ΔZ (Figure 2a) is due to inaccurate
178 temperature profiles, the observed range is ~ 4.5 km. That extreme value of ΔZ could occur for D_e
179 $= 180 \mu\text{m}$ and $\text{IWC} = 0.01 \text{ gm}^{-3}$ (Figure 3c) or for smaller values of IWC and D_e (Figure 3b), but
180 is unlikely to occur for very small particles (Figure 3a). The average bias at $Z_{eff} = 14$ km (Figure
181 2a) is 2.1 km, a value that can be explained, at $\text{VZA} = 14^\circ$, with uniform or decreasing IWC =
182 0.014 gm^{-3} and $D_e = 80 \mu\text{m}$ (Figure 3b), or with smaller or larger values of IWC and D_e . For a
183 given value of IWC, ΔZ in Figures a-c is similar for both the uniform and decreasing IWC
184 profiles, except that, for a given ΔZ , the IWC is slightly smaller for the decreasing case. For the
185 increasing-with-height case (not shown), ΔZ rapidly approaches zero with increasing IWC for all
186 particle sizes.

187 The decreasing-with-height IWC profile is probably most realistic, however, for
188 simplicity, only the uniform IWC case results are considered in the following calculations.
189 Although its value at 5 km is $62 \mu\text{m}$, the CERES-MODIS observed mean D_e varies almost

190 linearly from 55 μm at $Z_{eff} = 6$ km to 76 μm at 12.6 km, then down to 64 μm at 15 km (not
 191 shown). At 14 km, $D_e \sim 68$ μm , requiring IWC to be ~ 0.011 gm^{-3} . At $Z_{eff} = 9$ km, $\Delta Z = 1.6$ km
 192 and $D_e = 68$ μm , requiring IWC = 0.019 gm^{-3} . Since the optical depth corresponding to ΔZ is
 193 relatively constant (Figure 3d and other IWC cases), IWC can be estimated at each altitude using
 194 the proportional relationship

195

$$196 \quad \text{IWC} = k D_e / \Delta Z, \quad (4)$$

197

198 where ΔZ is determined from Eq (1), D_e is the mean at Z_{eff} , and the proportionality constant k
 199 was determined from Eq (4) to be 0.000334 gm^{-3} , using the estimate of IWC for $Z_{eff} = 14$ km and
 200 $D_e = 68$ μm . Values of uniform IWC were estimated for $Z_{eff} = 5 - 15$ km and fitted using a third
 201 order polynomial regression to obtain

202

$$203 \quad \text{IWC} = 0.018 \text{ gm}^{-3} - 0.000474 Z_{eff}, \quad (5)$$

204

205 where Z_{eff} is in km. The R^2 equals 0.77 indicating that the average IWC is strongly dependent on
 206 cloud height. This fit does not apply below 5 km. While the mean IWC varies between 0.01 and
 207 0.02 gm^{-3} , it is somewhat sensitive to the IWC vertical profile and much larger or smaller values
 208 of IWC could result from any individual CERES-MODIS/CALIPSO data pair.

209 The behavior of (5) is not surprising given that IWC has been observed to decrease with
 210 decreasing cloud temperature. (T_{eff} was not used as the independent variable here because the
 211 height differences were more highly correlated with Z_{eff} than with T_{eff} .) *Heymsfield and Platt*
 212 [1984] reported that the mean IWC in cirrus clouds varied from 0.027 gm^{-3} at $T = -25^\circ\text{C}$ to 0.001

213 gm^{-3} at -58°C and that IWC variability at a given temperature was typically an order of
214 magnitude or greater. *Wang and Sassen* [2002] found IWC ranging from 0.017 to 0.001 gm^{-3}
215 between -20 and -70°C for comparable clouds. *Garrett et al.* [2005] observed IWCs as large as
216 0.3 gm^{-3} in a thick anvil cloud, while smaller values, ranging from 0.0001 to 0.02 gm^{-3} , were
217 observed by *McFarquhar and Heymsfield* [1996] in the top 2 km of three tropical anvils. The
218 mean IWC values estimated here for the top portions of thick ice clouds are well within the range
219 of observations. The variation in the observed IWC's can also explain much of the random error
220 seen in Figure 2b.

221 Figures 3e and f show that the top-layer τ , constant at ~ 1.15 for $D_e = 80$ and $180 \mu\text{m}$,
222 increases up to 1.5 for $D_e = 10 \mu\text{m}$ (Figure 3d) and to larger values when $\text{IWC} < 0.01 \text{ gm}^{-3}$. The
223 corresponding values for the decreasing IWC case are 0.9 and 1.2 for $D_e = 80$ and $10 \mu\text{m}$,
224 respectively, and slightly greater for the increasing IWC case. The values of τ for the larger
225 particles are close to that used by *Sherwood et al.* [2004] to estimate where Z_{eff} should be relative
226 to the lidar-observed top for convective anvils. The difference is mostly due to scattering. Based
227 on the lidar-derived optical depths, *Sherwood et al.* [2004] concluded that the large values of ΔZ ,
228 similar to those in Figure 2a, did not correspond to $\tau = 1$, but to $\tau \geq 10$. Given the above analysis
229 and the observed range of IWC, it appears that an average value of 2 km for ΔZ is quite
230 reasonable and corresponds to $\tau \sim 1$ for the size of ice crystals retrieved with VISST. For the
231 matched CALIPSO-CERES data used here, the mean height where the CALIPSO beam was
232 fully attenuated is 1.3 km below Z_{eff} , a value much greater than the 150 m calculated for the
233 airborne lidar used in the *Sherwood et al.* [2004] analysis. It is not clear why that earlier analysis
234 produced such different results from the current analysis, but, may be due to assumptions used in

235 the τ retrievals from the airborne lidar or differences in power between it and the CALIOP.
236 Nevertheless, the current results are consistent with the expected values of IWC near cloud top.

237 The optical depths in Figure 3 decrease with VZA as expected. While the small range (9°
238 -19°) in VZA for this study precludes development of an empirical correction for VZA
239 dependence, the plots in Figure 3 suggest a simple cosine variation. Thus, calculating Z_{top}' using
240 either Eq (1) or (2), the VZA-corrected estimate of Z_{top} is

241

$$242 \quad Z_{top} = Z_{eff} + \Delta Z, \quad (6)$$

243 where $\Delta Z = \mu (Z_{top}' - Z_{eff})$. Validating Eq (6) will require a comprehensive combined imager-
244 lidar dataset having a wide range of VZAs.

245

246 **5. Concluding Remarks**

247 The effective cloud radiating height, Z_{eff} , may be adequate for radiative transfer
248 calculations in climate or weather models, but the physical boundaries of a cloud are needed by
249 models to determine where condensates form and persist. The upper boundary is inadequately
250 represented by Z_{eff} for ice clouds. This paper has developed a simple parameterization that uses
251 Z_{eff} to provide, on average, an unbiased estimate of Z_{top} for optically thick ice clouds. It
252 complements the parameterizations used to estimate Z_{top} for optically thin cirrus. The random
253 errors in Z_{top} determined with the new parameterization are consistent with the variations in ice
254 water content observed near cloud top in previous in situ measurements. Reducing the
255 instantaneous uncertainty in Z_{top} may be possible using combinations of different spectral
256 channels or dual-angle views, but the reduction will be limited by the accuracy of the
257 temperature profile. When applied, the parameterization estimate of Z_{top} should have some level

258 above the tropopause as an upper limit to minimize unrealistic results. If the observed cloud
259 penetrates into the stratosphere, however, Z_{eff} and, hence, Z_{top} can be underestimated because the
260 VISST selects Z_{eff} as lowest the altitude where where T_{eff} is found in the sounding. Additionally,
261 the correction should not be applied to low-level clouds. Although this new parameterization of
262 Z_{top} has been formulated in terms of Z_{eff} determined from the 11- μm brightness temperature, it is
263 probably applicable to Z_{eff} determined using other techniques such as CO₂ slicing. Although only
264 1 month of CALIPSO data was used here, the results appear robust. Testing with data from other
265 seasons would be required to confirm that contention and data from other satellites, that are not
266 near the CALIPSO ground track, would be needed to verify the formulation for off-nadir angles.
267 With an expanded dataset, it may also be possible to refine the correction in terms of cloud type
268 (e.g., cirrus, anvil, or convective core).

316 **Figure Captions**

317

318 **Figure 1.** CALIPSO products for 27 April 2007. (a) CALIOP backscatter intensities, (b)
319 CALIPSO feature mask with overlaid CERES-Aqua-MODIS cloud-top heights Z_{top} for single-
320 layer optically thick ice clouds, (c) same as (b) except Z_{top} corrected with Eq (1).

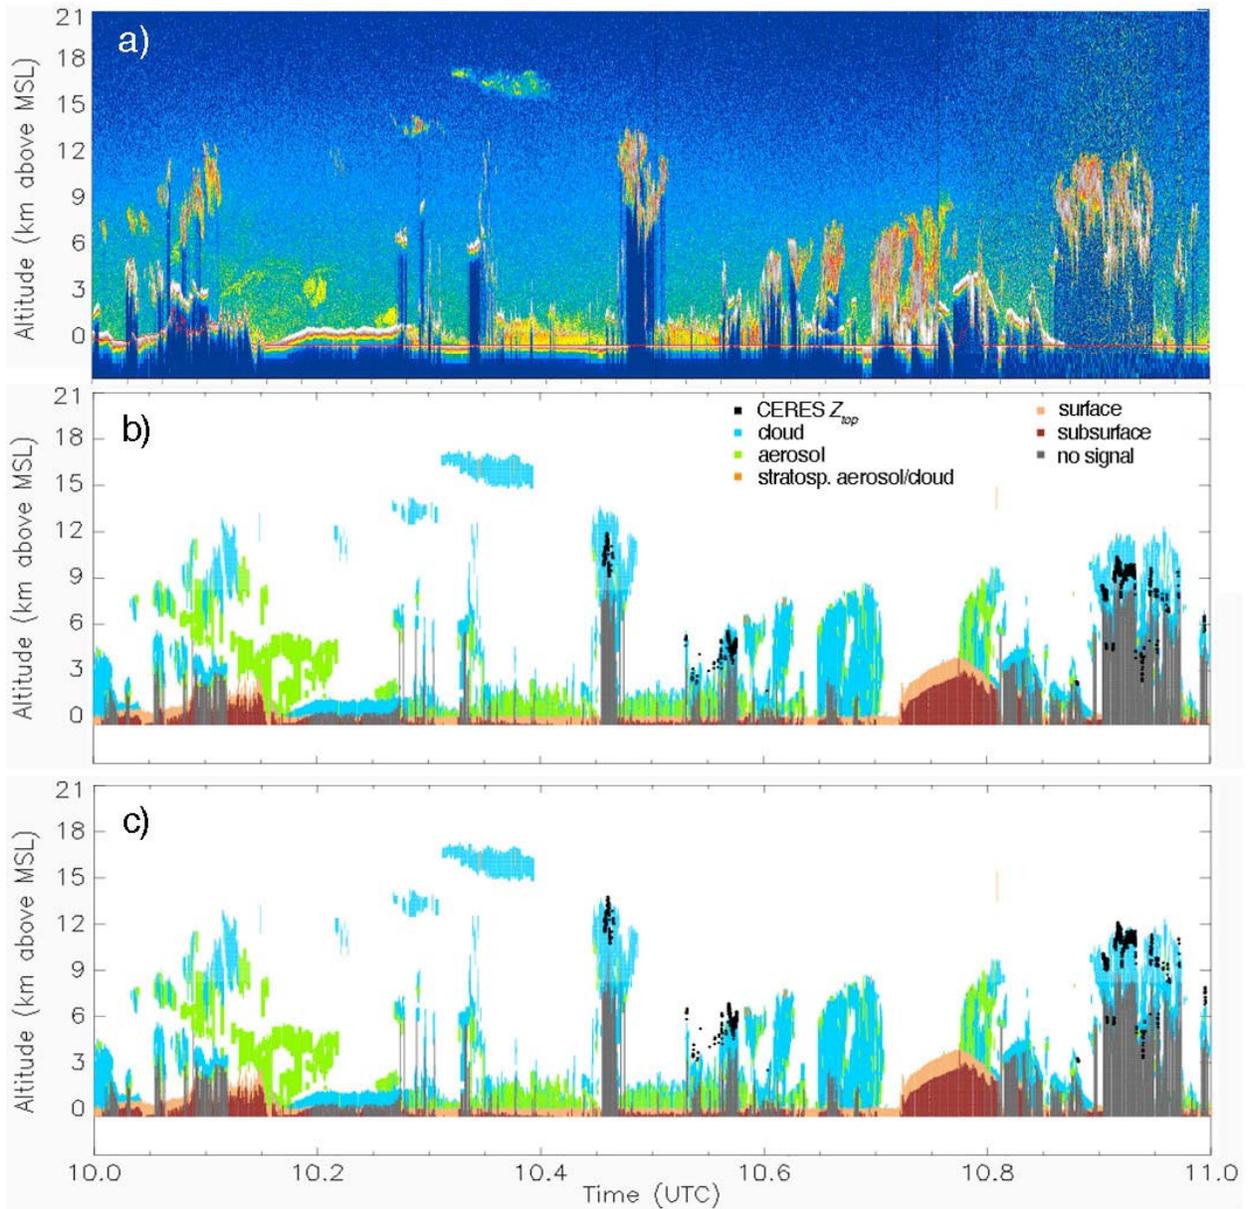

321

322 **Figure 2.** Scatter plots of CALIPSO optically thick non-polar cloud-top altitudes during April
323 2007 versus (a) Z_{eff} for even days and (b) Z_{top} computed from Z_{eff} using Eq (1) for odd days.

324

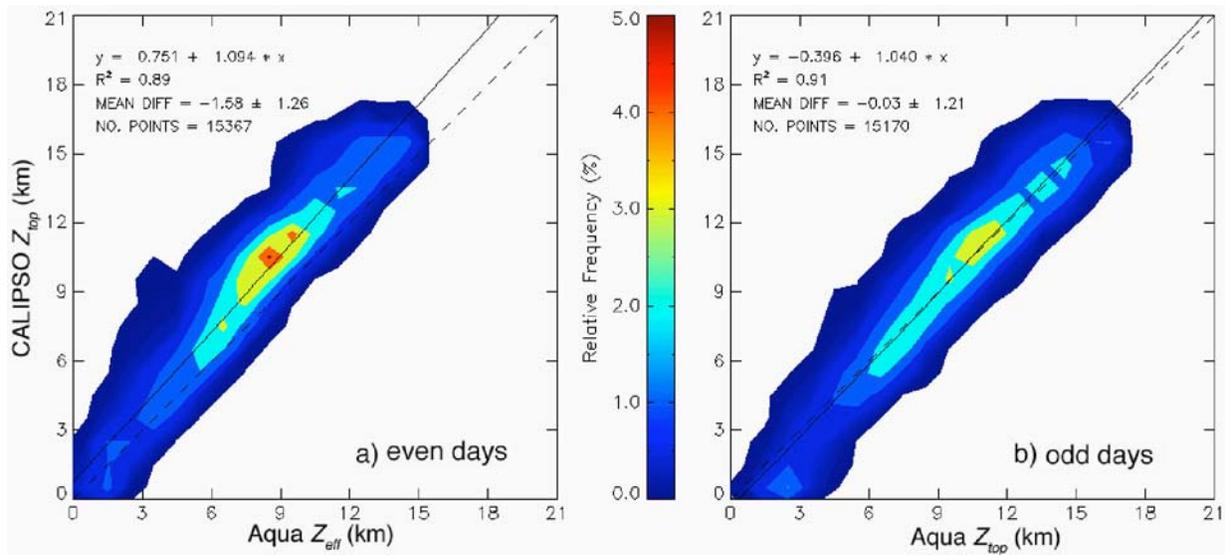

325 **Figure 3.** Theoretical variation of (a-c) cloud-top/effective height difference (ΔZ) as function of
326 IWC and (d-f) optical depth of cloud layer above Z_{eff} as function of ΔZ . Main panels are for
327 uniform IWC in the cloud, while insets are for IWC decreasing with increasing height in the
328 cloud.

329

330
 331 **Figure 1.** CALIPSO products for 27 April 2007. (a) CALIOP backscatter intensities, (b)
 332 CALIPSO feature mask with overlaid CERES Aqua MODIS cloud top heights Z_{top} for single-
 333 layer optically thick ice clouds, (c) same as (b) except Z_{top} corrected with Eq (1).

334
